Key Message: We estimated aboveground biomass of large mangrove trees from terrestrial Lidar measurements. This makes the first attempt to extend mangrove biomass equations validity range to trunk diameter reaching 125 cm.

Abstract

Accurately determining biomass of large trees is crucial for reliable biomass analyses in most tropical forests, but most allometric models calibration are deficient in large trees data. This issue is a major concern for high-biomass mangrove forests, especially when their role in the ecosystem carbon storage is considered. As an alternative to the fastidious cutting and weighing measurement approach, we explored a non-destructive terrestrial laser scanning approach to estimate the aboveground biomass of large mangroves (diameters reaching up to 125 cm). Because of buttresses in large trees, we propose a pixel-based analysis of the composite 2D flattened images, obtained from the successive thin segments of stem point-cloud data to estimate wood volume. Branches were considered as successive best-fitted primitive of conical frustums. The product of wood volume and height-decreasing wood density yielded biomass estimates. This approach was tested on 36 A. germinans trees in French Guiana, considering available biomass models from the same region as references. Our biomass estimates reached ca. 90% accuracy and a correlation of 0.99 with reference biomass values. Based on the results, new tree biomass model, which had $R^2$ of 0.99 and RSE of 87.6 kg of dry matter. This terrestrial LiDAR-based approach allows the estimates of large tree biomass to be tractable, and opens new opportunities to improve biomass estimates of tall mangroves. The method could also be tested and applied to other tree species.

Keywords: Aboveground biomass; Coastal blue carbon; French Guiana; Mangrove; Terrestrial LiDAR; Tree allometry

Introduction

Recent studies have highlighted the importance of large trees as keystone ecological elements (Lindenmayer et al. 2012; Lutz et al. 2013) in forest ecosystems. The significance extends beyond the characteristic contribution to regeneration as mother trees and the provision of food and shelter for many living organisms, because they also represent the principal structures shaping ecosystem biomass productivity and recurrent forest dynamics (Slik et al. 2013). In terms of wood volume, biomass, and carbon stocks, they dominate the forest structure and this may explain variations in biomass distribution across forest landscapes (Bastin et al. 2015a). Thus, an accurate estimation of the biomass of large trees is crucial for obtaining reliable estimates of the total biomass in such forests.

One key challenge is that the biomass data of large tropical tree are generally scarce (e.g. only ca. 7% of the available pantropical tree biomass dataset, Chave et al. 2014). This is also the case for the tall mangroves that
grow in the equatorial region. Although the species diversity of mangroves is low compared with rainforests, the variability in the tree structure of *Avicennia* species, for example, is higher. *Avicennia* trees may exhibit a wide range of growth forms, from small to large/tall trees, depending on the habitat condition. Considering this variation in tree structure, available models may actually fall short in their predictive power for out-of-sample application. This situation also appears a limitation on the extent to which the existing general pantropical biomass allometric models can be applied to mangrove trees, without significant bias in the resulting estimates. Meanwhile, there is a growing interest in attaining highly precise estimates of biomass and carbon stock of tropical forests (Gibbs et al. 2007; Pistorius 2012), including mangroves, as in the case of the blue carbon projects. This necessitates the refinement of the available methods, like the commonly used allometric models, and the development of unbiased protocols for biomass measurement. Currently, the available biomass models for mangrove trees (Komiyama et al. 2008) only cover a range of small-medium sized trees \((DBH \leq 50\) cm) and are deficient in respect of large trees. Collecting data, using the conventional cutting and weighing method, to validate mangrove biomass models for large trees is however difficult in the tidal environment. The terrestrial laser scanning (TLS), also known as terrestrial LiDAR (light detection and ranging), offers a remote sensing technology that allows capturing the high resolution three-dimensional (3D) structure of trees with relatively low time and labour requirements. Earlier applications in the forest sciences and ecological studies include the description of forest structural parameters (Strahler et al. 2008), assessment of canopy metrics and gaps (Bayer et al. 2013; Coops et al. 2007; Hilker et al. 2010), individual tree volume and biomass estimation (e.g. Calders et al. 2015; Dassot et al. 2012), to the application in estimating leaf area and foliage properties (Béland et al. 2014; Huang and Pretzsch 2010). Interestingly, various approaches have tested satisfactorily in the estimation of individual tree volume and biomass from TLS point cloud data: from the use of tree features extraction (Kankare et al. 2013; Pueschel et al. 2013), shape reconstruction and primitive fittings (Raumonen et al. 2013; Yu et al. 2013) to voxelization (Hauglin et al. 2013).

Some automatic techniques have been proposed for reconstructing and modelling of tree structure and topology (Akerblom et al. 2015; Hackenberg et al. 2014; Raumonen et al. 2013), and they achieved notably good results with regular, cylindrical shaped tree trunks, and mostly in leaf-off conditions. Since such methods are based on segmental geometric primitive fits, irregularities in the shape of large tropical trees like mangroves remain challenging for direct application of such automatic tree reconstruction. For irregular trunk shapes, we presume that automatic techniques may require a combination with (semi-)manual interactive steps. All the same, the application of TLS in the study of mangrove species remains largely unexplored; the only pilot attempt was limited to mangrove trees with \(DBH < 43\) cm (Feliciano et al. 2014). In the present study, our aims were (1) to describe and evaluate the performance of a simple TLS-based method for estimating the wood volume and biomass of large mangrove trees, and (2) to propose revised allometric models for the widespread mangrove tree species *Avicennia germinans* (L.) L. with a validation domain extended to very large trees.

**Methods**

**Study area**

The study was performed in French Guiana (hereafter referred to as FG) where mangroves stretch along a 320 km coastline (Appendix 1), to cover an approximate area of 70,000 ha. This coast can be considered as pristine, because there are still no extensive industrial activities, and aquaculture and tree exploitation are not present. It is subjected primarily to sediment dispersal from the Amazon River (Baltzer et al. 2004). The spatiotemporal distribution of mangroves is controlled by a succession of rapid and acute erosion and accretion phases caused by the drifting of giant mud-banks to the northwest of the coastline (Anthony et al. 2010). The mangrove forests encompass new colonization on the freshly consolidated mud-banks up to mature forests located several kilometers inland at the limit of tidal influence. In this area, mangroves are unaffected by coastal instability (Anthony et al. 2010) and this allows trees to reach their largest potential stature. Fromard et al. (1998) described the different mangrove forest types of FG; *A. germinans* (L.) L. is represented from pioneer to old-growth forest, spanning a wide range of growth stages. These growth stages are patchily distributed across the coastal landscape with clusters of young trees, sometimes in close vicinity to decaying stands (Proisy et al. 2007).
The sampling locations were selected in order to capture data from trees distributed over a wide DBH range. This DBH range was distributed in three distinct forest stands. (Appendix 1). First, a mixed old-growth Avicennia–Rhizophora forest stand near Petit Cayenne 10 km upstream of the Cayenne river, with a stand density of 504 trees per hectare, total basal area of 26.2 m².ha⁻¹ and A. germinans trees reaching a mean DBH of 56.2 cm. The second stand, located at about 3 km from the actual mangrove shoreline along Guatemala road, was made up of small-medium size and scattered large A. germinans trees. The tree density in this stand was 3733 trees per hectare with a total basal area of 25.5 m².ha⁻¹, and average DBH of 15 cm. The third stand was an even-aged A. germinans forest located 6 km backward of the mangrove seafront in the Sinnamary region. This stand contained mainly A. germinans in a density of 1132 trees per hectare with basal area totalling 21.8 m².ha⁻¹.

**Essential features of Avicennia germinans (L.) L.**

In this study, we employed A. germinans as a proxy species to test a new method for estimating the biomass of mangrove trees using TLS data. This is a keystone species and the most dominant mangrove species on the FG coast (Fromard et al. 1998, Fromard et al. 2004). A. germinans trees vary greatly in size and growth form. The species grows from low-scrubby (ca. 0.4–1.5 m tall) in the sub-optimal habitats (Vogt et al. 2014) to large trees approaching 42 m height and 125 cm diameter in favorable and stable growth conditions, as found in some regions of FG. Trunks are roughly cylindrical to slightly angled or even canaliculated and may develop buttresses and short fascicles of aerial roots. The trees reiterate to produce coppice shoots when the main stem is damaged, resulting in frequently contorted stem development.

**Existing biomass allometric models for A. germinans**

Fromard et al. (1998) developed biomass allometric models for aboveground biomass (AGB) of mangrove trees in FG. The models for A. germinans followed a power function, with two coefficients (Table 1). They were calibrated using data obtained from small to medium-sized trees with DBH of 4 – 42 cm and corresponding AGB between 4.8 and 1543.7 kg of dry matter, respectively.

The coefficients α (intercept) and β (slope) are constant parameters, and n is the number of sample trees.

These models conformed to the biomass allometric model developed for the same species in Guadeloupe (Imbert and Rollet 1989). Other mangrove biomass models applicable to A. germinans are the two generic equations developed by Chave et al. (2005) and Komiyama et al. (2005), which were also calibrated with trees DBH < 60 cm. An independent dataset obtained by direct cutting and weighing of sample trees (Fromard et al. 1998) at the same study locations as ours jointly with the predicted biomass estimates of currently sampled trees, using the allometric models of Fromard et al. (1998), were used for reference to evaluate the TLS-based biomass values and new models presented in this study.

**Wood density (WD) measurements at different heights**

In most studies of allometric relationships, the WD is estimated at breast height. To our knowledge, no WD measurements have been reported at different heights along the main axis for A. germinans so far. Thus, we initiated an experiment that involved coring A. germinans trees at different heights in various mangrove regions throughout FG. We climbed 20 trees (10 < DBH < 110 cm) and used hand-powered drills to extract 52 samples. The wood core samples measured 4.3 mm in diameter with lengths of 2–13 cm over bark. The core heights along the stem axis ranged from 0.3 m for all trees up to 23 m for tall trees, corresponding to diameters varying from 4.8 cm, at the top of small trees, up to 110 cm at the base of large trees. All core samples were dried at a constant temperature of 105 °C for several days until constant mass, and subsequently weighted in relation to wood volume to obtain WD as dry weight. High variability in the WD was observed at heights below 10 m, and also around the breast height.
The distribution of wood density along the main stem vs. sampling height and diameter was fitted using a linear mixed effects (LME) model, with the individual tree as random factor. This analysis was based on \( WD \) data from the outer wood core samples, since the outer \( WD \) values are known to strongly correlate to the \( WD \) values from any point along the radial spectrum, without a significant bias (Bastin et al. 2015b).

**TLS measurements and data processing**

The TLS measurements used in this study were collected with a FARO Focus3D X330 device between August and September 2014. The instrument operates using a 1.55 \( \mu \text{m} \) class 1 laser signal. The distance between the scanner and the object is determined by analyzing the shift in the wavelength of the return beam. The device can scan objects at a distance of up to 330 m; and with an accuracy of < 0.25 mm for dark objects at a distance of 25 m. The vertical and horizontal fields of view are 300° and 360°, respectively. Several scanning resolutions can be used for collecting point cloud data from the focal surface. However, we chose the second finest scanning configuration able to achieve complete scanning at about 20 min with a distance accuracy reaching ±3 mm over a horizontal range of 90° as the finest scan required more than 1 hour for an accuracy slightly improved to ±2 mm over the same distance. A flowchart that illustrates the procedure for data acquisition and subsequent processing is presented in Fig. 1. More detailed methodical descriptions are provided in the subsequent sections.

![Flowchart](image-url)

**Fig. 1** Scheme of procedure for TLS data acquisition and processing in mangrove tree biomass estimation. AG = aboveground, \( WD \) = wood density, \( mWD \) = mean \( WD \) value at tree DBH, and \( dWD \) = decreasing value of \( WD \) with height along the stem axis.

**Mangrove tree scanning**

The number of trees selected for each scanning operation ranged from a single (large) tree to a group of six individual (small to medium-sized) trees. Before placing the instrument, several viewpoints were identified for TLS placement around selected
individual(s), and subsequently distribution of the target spheres (reference objects to aid merging/alignment of multiscans). This was a crucial step because it directly affected the quality of the 3D description of the focal mangrove tree(s). In this experiment, five white target spheres were positioned in the foreground and background surrounding the focal trees at different heights ranging from 0–2 m using stands made of metal rods and pipes, at a minimum distance of ca. 3 m from the tree base (Appendix 2). The TLS instrument was mounted on a sturdy tripod stand, with additional support from reinforced metal frames (ca. 60 cm long) embedded in the muddy sediment. One can adapt the length of these support metal frames as required, until adequate stability is reached before mounting the LiDAR system. The number of scan positions was selected as a function of the horizontal and vertical projections of the target trees. To minimize the chance of occlusions or missing parts in the 3D tree structure, it was essential to scan large individual trees with buttresses from at least 5 viewpoints at high scanning resolution. Summary descriptions of the sample trees are presented in Table 2.

**Extraction of trunk and branches from point-cloud data**

The TLS data processing comprised merging of multiple scans, filtering or removal of background vegetation, and generating point clouds for individual trees of interest. This process was conducted using the FARO SCENE 5.2 software. The process took from ca. 1 - 12 working hours to complete one large tree, depending on its structure. The main trunk and primary branches (in the case of large trees) were manually separated, and the 3D coordinates of the point cloud were exported for subsequent processing. The computation routine for wood volume and biomass was implemented in MATLAB. For control, we also fitted successive geometric primitives on point cloud data of trunks and branches (> 4 cm at the branch base) using the least squares method.

**Computation of the trunk and branch volumes**

Two volume computation procedures were performed for the trunks: (1) volume estimation of successive best-fitted geometric shapes (primitive fitting), and (2) an automatic pixel count on 2D flattened projection of segmented thin trunk sections. The trunk volume estimates from the composite primitive shapes fitted on the selected trunks served for the validation of the pixel-based analysis. The determination of the volume of tree branches was restricted to manual primitive shape fittings in this study due to computational complexity.

**Stem volume estimation by primitive fitting**

For each tree, sets of conical frustums were extracted that corresponded to the main trunk and each branch. The diameters at the base (Db) and the top (Dt), and the height (Hc) of each solid shape were recorded. Thereafter, the geometrical volume (Vc for trunk and Vcb for branches) of each primitive shape was estimated as a truncated cone, as given by equation 1.

\[ V_{c_i} = \frac{\pi \cdot H_{c_i}}{12} \left( D_{b_i}^2 + D_{t_i} \cdot D_{t_i} + D_{t_i}^2 \right) \]

All of the Vc values in a trunk were summed to obtain the trunk volume. The addition of the component Vcb of each branch yielded the branch volume.

**Trunk volume estimation with the pixel-based method**

We implemented a program routine that decomposed 3D trunk shapes into successive thin sections (Fig. 2a–c). The height of each section to the ground level was recorded. These sections were converted into two-dimensional (2D) binary images to obtain their flattened plan projections. Different segmentation heights (section thickness), ranging from 1 cm to 1 m, were tested to find a trade-off between complete shape outline and gaps in the 2D plan. When open shapes occurred in the point cloud (due to occlusion on trunk part during scanning), they were filled automatically by fitting a simple convex envelope around the missing region. The area covered by the boundary of the section was then divided into a grid of 1 cm² pixels. The number of pixels in the flattened image of each section was summed to obtain its surface area, and the volume was obtained as the product of the surface area and its thickness, and the trunk volume was obtained as the total stacked constituent sections. These trunk volume estimates were compared with the volume obtained from primitive fittings (described above) to validate the pixel-based method.

**Biomass estimation from TLS-derived wood volume**

**Conversion of stem volume to biomass**

In this study, we systematically obtained two biomass estimates: the first used a mean WD derived from our wood density sampling; and the second employed a decreasing WD relative to height along the stem axis.
derived from the respective linear mixed-effects model. In the latter case, we interpolated the height WD model to obtain specific WD at each section height by reference to the bottom of the tree. The biomass estimates for each of the trunk (BTR_{TLS}) and the branch (BBR_{TLS}) components were obtained as the sum of the products of each section volume and the corresponding WD. The sum of the branch and trunk biomass of each tree provided its TLS-derived aboveground woody biomass (AGBW_{TLS}). The leaf biomass was only considered in this study as a proportional relation following the model of Fromard et al. (1998) in Table 1, although it constituted an insignificant share of the AGB estimates.

**Evaluation of TLS biomass estimates for trees DBH < 42 cm**

We applied a cross-validation procedure to evaluate the accuracy of the TLS-derived trunk volume and biomass estimates of trees within the DBH range of the reference data (Fromard et al. 1998). We calculated the root mean squared error (RMSE) and the accuracy using equations 2 and 3, respectively:

$$
\text{RMSE} = \sqrt{\frac{\sum_{i=1}^{n} (FF_i - TLS_i)^2}{n}},
$$

$$
\%\text{RMSE} = 100 \cdot \frac{\text{RMSE}}{\text{mean}(FF)},
$$

where $FF_i$ denotes the reference values based on Fromard et al. (1998), $TLS_i$ is the corresponding TLS-derived estimate, and $n$ is the number of trees.

**Fig. 2** Trunk segmentation and sectioning for stem volume computation. a) Typical view of a large mangrove tree. b) A trunk with $DBH = 93.5$ cm. c) Typical flattened projection of a trunk section extracted at a height of 1.3 m

**Fitting of allometric models using TLS-derived biomass data**

**Model calibration**

We employed TLS-derived data for calibrating easily applicable biomass allometric models. Based on tree diameter–biomass relationship of *A. germinans*, we fitted a new non-linear AGB model with DBH as the predictive variable using a maximum likelihood regression approach (M1, equation 4). The coefficients $\alpha$ and $\beta$ are parameters that characterized the new biomass models we obtained. As suggested by Chave et al. (2005) and Komiyama et al. (2005), we considered...
other models (M2–M4) that incorporated WD (denoted as $\rho$ in the allometric equations) and/or tree height ($H$), as given by equations 5–7:

M1: \[ AGB = \alpha \cdot DBH^\beta + \varepsilon, \]

M2: \[ AGB = \alpha \cdot \rho \cdot DBH^\beta + \varepsilon, \]

M3: \[ AGB = \alpha \cdot (DBH^2 H)^\beta + \varepsilon, \]

M4: \[ AGB = \alpha \cdot \rho \cdot (DBH^2 H)^\beta + \varepsilon, \]

where $\varepsilon$ is the model error, which considers factors that may explain the difference in biomass between two trees with the same DBH and H dimensions. The branch ($BBR.M$) and trunk ($BTR.M$) models were fitted according to the model formulated in M1. All of the variables in these models were considered as logarithmic transformed variables to eliminate heteroscedasticity. To obtain biomass values by back-transformation, we applied the correction factor (CF) described by Sprugel (1983), which relies on the residual standard error (RSE) of the models, as given in equation 8, thereby adjusting for the systematic bias associated with log-transformations of data.

\[ CF = \exp \left( RSE^2 \right) \]

Evaluation of the biomass models

A thorough validation of a new model normally requires the use of independent empirical datasets (Vanclay and Skovsgaard 1997). However, due to the relatively small sample size and paucity of separate validation datasets, we decided to employ goodness-of-fit statistics, Akaike’s information criterion (AIC) for multi-model inference, and graphical analysis to assess the performances of the new models in comparison to the previous models produced by Fromard et al. (1998). All of the model fitting procedures and statistical evaluation were performed using MATLAB.

Results

Height-dependent wood density

WD values ranged from 595 to 790 kg m$^{-3}$ (Fig. 3) for trees over a DBH range of 10.4 – 110 cm, with a mean value of 728.7 ± 8.91 kg m$^{-3}$ around the breast height.

Fig. 3 Decreasing wood density at different heights along the stem axis: black dots denote the wood density values obtained from various tree samples; the green dot was considered an outlier; and the dashed line shows the linear model with a 95% confidence interval in blue

The LME model fitted for WD as a function of sample height and tree DBH, with the individual tree as a random factor, demonstrated a decreasing trend along the stem axis. From the tree base to the top, each increase in the sampling height resulted in a 0.7% decrease in the basal mean WD value of 731.5 ± 17.2 kg m$^{-3}$. The inclusion of a measure of individual tree DBH in the model resulted in ca. 0.08% increase in the predicted ($P = 0.076$). Thus, individual tree effect was not a significant factor in the total effects found in the distribution of wood density along the stem axis.

Accuracy of pixel-based trunk volume estimation from TLS data

Based on the performance test of the pixel-based method, the best results were achieved at a trunk section height of 10 cm during volume computation. These trunk volume estimates were compared with the geometric volume based on successive conical frustums for the analyzed trees (Fig. 4a). The RMSE between these two methods reached 6.7% of the mean value for 18 trees with no pronounced buttresses. The linear fit ($R^2 = 0.99$) of the trunk volume estimates nearly overlaid the one-to-one line for the small, almost straight bole trees (Fig. 4a). Higher volume estimates were obtained from trees with more pronounced buttresses, with the RMSE value increased to 16.7% of the mean value and the $R^2$ decreased to 0.96 for larger
trees (Fig. 4b). Overall, the pixel-based method produced trunk volume with an accuracy of ca. 90%.

**Accuracy of TLS-based tree volume-to-biomass conversion**

The two specific WD values were combined with the pixel-based trunk volume estimates to produce biomass of trees in the diameter range of the reference data. The mean value of WD yielded a mean deviation of 16.5% (dry matter) compared with the reference biomass values for tree DBH < 42 cm. The dWD values lowered the mean deviation of the TLS-derived trunk biomass to 6.7% for the trees analysed in this study. Overall, the dWD-based biomass estimates strongly correlated with the reference values (R = 0.99), where the RMSE was 41.23 kg (14.21%) for the trunk biomass, 48.6 kg (13.6%) for the aboveground woody components, and 48.5 kg (13.5%) for the total AGB (Fig. 5a–c), with biomass values ranging from ca. 70 to 900 kg (dry matter).

**Aboveground woody biomass of large A. germinans trees**

The sum of the TLS-derived branch and trunk biomass yielded the aboveground woody biomass of large trees. These values ranged from 1242 kg for a tree with a DBH of 44.9 cm to 17,367 kg for a tree with a DBH of 124.5 cm. The branch biomass composition was almost uniform in small to medium-sized trees, i.e., 15–20% of the tree biomass. For large trees, the branch biomass varied from ca. 20% to almost 50% of the tree AGB in some cases.

---

**Fig. 4** Comparison of the trunk volumes estimated using the automatic pixel-based analysis of TLS data and the successive trunk-fitted conical frustums for trees with DBH < 42 cm (a) and > 42 cm (b). Outline of girth form of typical trunks are shown above in white with a grey background (arrows 1–4). The dashed line depicts a one-to-one relationship and the blue solid line corresponds to linear fit.

**Revised allometric models of A. germinans trees**

Using the new TLS-derived tree biomass and the available tree weight dataset, revised allometric models’ parameters were proposed (Table 3). For the tree branch biomass (BBR.M), we obtained a model with the same intercept coefficient (α = 0.03) as the reference model (BBR_ref). Meanwhile, the model parameter β and R² changed from 2.33 and 0.90 to 2.41 and 0.98, respectively. The curve describing BBR.M clearly shifted upward for trees larger than the...
diameter range of BBR_{ref} (Fig. 6a), indicating that the BBR_{ref} underestimated the branch biomass of large trees. Our model for trunk biomass (BTR_{M}) was characterized by the model parameters $\alpha = 0.11$ and $\beta = 2.46$, which yielded a clear power curve deflection below the reference model (Fig. 6b). The $R^2$ also increased from 0.95 in the reference model ($BTR_{ref}$) to 0.99 in the BTR_{M}. We obtained the best fit for a total AGB (M1) model, which has DBH as an explanatory variable (Table 3, Fig. 6c). The model clearly had different parameters, where $R^2 = 0.99$ and corrected AIC were significantly lower compared with the reference model ($AGB_{ref}$), but the corresponding residual standard error (RSE) only decreased by 1.2 kg (1.4%). With the exception of M2, which is similar to M1 in terms of model parameter and statistical attributes, M3 and M4 models with additional variable(s) (tree height and wood density) yielded higher residual standard errors compared with the $AGB_{ref}$.

**Discussion**

In this study, we evaluated the possible use of TLS for estimating the AGB of large mangrove trees (*A. germinans*) to facilitate the development of improved, non-destructive measurement procedures and to achieve higher precision in allometric models.

**Accuracy of the TLS-derived mangrove tree biomass**

The results of the TLS-based biomass estimates reliably compare to the tree biomass weighed in the field for $DBH<42$ cm. In particular, the estimates for the small to medium-sized trees had an accuracy of near 90% and they were highly correlated ($R = 0.99$) with the reference biomass. Interestingly, the accuracy of results produced using our simplified TLS data analysis achieved a comparable accuracy with results reported in previous studies (e.g., Raumonen et al. 2013, Calders et al. 2015). That the presence of buttresses in trees (Nogueira et al. 2006) may influence the overall accuracy of the TLS-derived biomass estimates justified the consideration for a pixel-based analysis adopted in this study. This approach respects the real shape of buttressed trees, making it particularly suitable for biomass measurement in large mangroves trees where basal protuberance are present.

Additionally, the careful selection of thickness for trunk sections in the segmentation process, as well as the consideration for the WD variations along the stem axis during the biomass conversion contributed to a high precision of the TLS-derived biomass estimates. Notwithstanding, the approach that dwells on primitive shape fitting may be sufficient when trees are near perfect shaped cylinder or conical forms, as is with the case of small and medium sized trees. Overall, it is possible that the TLS-based measurement might insignificantly underestimate the actual tree biomass, especially for the crown biomass where the omission of fine twigs may likely occur.

*AGB = aboveground biomass, H height, p wood density, α and β coefficients, RSE residual standard error of estimates, AIC corrected Akaike’s information criterion, i.e., a measure of a model’s relative quality (the lowest AIC describes the best model), the BBR.M, BTR.M, M1–M4 are models extended to large trees and the BBR<sub>ref</sub>, BTR<sub>ref</sub> and AGB<sub>ref</sub> are the reference models.

**Modelling mangrove tree biomass with TLS-derived data**

Given the significance of large-diameter trees in allometric models, the new sets of biomass equations obtained in this study, which extend to very large trees, should improve biomass analyses of mangrove forests. The models do not yield significantly different predictions; model M1 where only DBH was used as an explanatory variable was shown to produce the best results according to the evaluation parameters. The TLS-based allometric models yielded new model parameters with higher predictive power, especially for the aboveground tree components of large trees.

It should be noted that the overestimation of the trunks of large trees in relation to the reference models was complemented by the corresponding underestimation from the branch model in the total AGB estimates, with the new model yielding only slightly lower AGB estimates for trees DBH > 42 cm. Contrary to our expectations, the current results thus suggest that the reference model presents considerably good estimates for the total AGB, even for the very large trees.

The distinction in the behaviour of our models for the branch and trunk biomass and the reference models can be explained by the variations in the pattern of biomass partitioning in the aboveground tree components beyond the DBH range of the reference models.

Fromard et al. (1998) confirmed that the small-medium size trees used to produce their models mostly had allocated the largest share of the AGB to their trunks, which was also demonstrated in our current study. The trees in these growth stages usually exhibit continuous growth in height and consistent natural pruning with no pronounced crown size. This growth pattern is likely related to survival strategies for fast-growing trees in competitive growing conditions. Later, trees will reach approach asymptotically a height where only secondary growth in the tree girth and the crown development continue, and large trees may prioritize biomass distribution to the branches on the assumption of a means for canopy space filling and to ensure mechanical stability. Since the allocation of biomass to different tree components is subject to environmental effects, we suggest that considering the plasticity of tree morphology in mangrove allometric models may greatly facilitate improved biomass prediction in a range of environmental conditions. Indeed, Peters et al. (2014) have demonstrated such an environment-related plasticity in a mechanistic approach in their BETTINA model. This and similar models can be parameterized with TLS-derived data to achieve a framework for accurate biomass analyses from natural scrubby to tall mangrove forests.

In this study, the allometric model where mean WD was incorporated slightly increased the residual error of the biomass predictions compared with the base model.
Since the WD varies with the individual tree size, but also at different heights within an individual A. germinans tree, it is possible that the use of global or site-specific mean values may result in more biased estimates. Nevertheless, this factor has greater importance when parameterizing allometric models for species-specific comparisons among different sites or in multispecies applications (Chave et al. 2005, Chave et al. 2014). In addition, the inclusion of tree height as an additional variable in the current allometric models incurred higher residual error to biomass estimates. More so that this variable is not always available and not easy to measure, we suggest that the allometric model based only on the DBH is sufficient for estimating the biomass of A. germinans trees under optimal growth conditions.

_Challenges affecting the wider application of TLS in mangrove studies_

The TLS provides an attractive, indirect method for the estimation of forest biomass, but several challenges need to be addressed to maximize its usability in mangrove studies. Deflection of tree crowns by the wind occurred during measurements in some of our scanning operations, especially with small to medium-sized trees. Thus, avoiding scanning during windy periods may reduce the likelihood of errors in such conditions.

In addition, large mangrove trees occasionally have hollow trunks due to rotting of the heartwood. This may lead to significant errors in the biomass estimates obtained for large trees based on indirect non-destructive measurements (Nogueira et al. 2006). However, it is questionable whether it is, in a real world scenario, feasible to reliably capture the necessary information on hollow trees, even from conventional destructive sampling. Without knowledge of the average volume of the cavities in the different tree size classes and the respective probability of their occurrence, subsequent estimation of biomass from regression models relying on DBH surveys will consequently fail, regardless of the calibration technique applied. Advances in the application of ultrasonic tomography (Brancheriau et al. 2008) and Resistograph measurements (Rinn et al. 1996) demonstrate non-destructive detection of volume of cavities in trees. Integrating these measurements with the TLS-based method in the future could address the uncertainty caused by the possible presence of tree cavities.

Fig. 6 Comparison of the TLS-based biomass functions and the reference models for A. germinans. The branch (a), trunk (b), and total AGB (c) are distinguished. The red line and the surrounding shade represent the new model and confidence interval. The dashed line is the prediction from the reference model, calibrated over the DBH range in the shaded area
Meanwhile, in the current study, we have carefully avoided hollow trunks by a systematic restriction of sampling to physically sound trees (i.e., without signs of crack or rotten parts).

By considering the individual architecture of trees, our proposed TLS-based method could have wide applicability to other mangrove species. The work of Feliciano et al. (2014) already demonstrated a workaround for TLS application to Rhizophora species, considering the prop roots as toroidal objects to estimate their volumes and biomass. Their approach and the one presented here are fundamental towards ensuring the wider applicability of the TLS method for the studies on mangrove tree architecture and ecosystem functioning. The approaches could also be supported by tree architecture studies, which are scarce for mangroves at present, for example, for species developing prop roots, or aerial appendages.

Conclusively, the TLS data analysis provides a viable substitute for the destructive biomass measurement and allows estimates of large mangrove trees to be tractable. This opens new research opportunities in mangroves studies with respect to tree architecture, biomass productivity and ecosystem functioning. Our current allometric models may facilitate accurate determinations of the biomass for the aboveground parts with potential benefit to the success of the coastal blue carbon projects for conservation of mangrove forests. To advance the TLS method to other mangrove forests, a fully automatic procedure for volume and biomass estimation is desirable for use in the natural scrubby to tall mangrove forests, and this may require further refinement of our current procedure for TLS data collection and processing.
