A B S T R A C T

To understand the causes and patterns of shark attacks on humans, accurate identification of the shark species involved is necessary. Often, the only reliable evidence for this comes from the characteristics of the wounds exhibited by the victim. The present case report is intended as a reappraisal of the Luengoni, 2007 case (International Shark Attack File no. 4299) where a single shark bite provoked the death of a swimmer by haemorrhagic shock. Our examination of the wounds on the body of the victim, here documented by so-far unpublished photographic evidence, determined that the shark possessed large and homodontous jaws. This demonstrates that the attacker was a tiger shark, not a great white shark as previously published.

Keywords: shark attack; wound; misidentification; ISAF; New Caledonia

1. Introduction

New Caledonia's shark fauna has at least 48 species.¹ This list includes several large species recognized as dangerous to humans, namely: the bull shark, *Carcharhinus leucas*, the tiger shark, *Galeocerdo cuvier*, and the great white shark, *Carcharodon carcharias*.^{2,3} There is widespread admission that dangerous encounters of sharks by humans in a recreational context have increased in New Caledonia in recent years,^{3,4} as in other regions.^{5,6} A possible explanation of this trend might well be that human frequentation of the New Caledonian reef and lagoon also increases from year to year.⁷ So far, eight fatal shark attacks have been reported from New Caledonia.^{3,4,8} Three of these attacks have been recorded in the International Shark Attack File (ISAF) of the Florida Museum of Natural History, Gainesville, under numbers c3214, 4299 and 4522. The description of case no. 4299 has been published previously.⁹ The authors, E. Clua and B. Séret, ascribed the attack to the great white shark, *Carcharodon carcharias*,⁹ but this interpretation differs from other accounts.^{3,4,10} As explained in their paper,⁹ E. Clua and B. Séret acknowledged that their description was based on interviews of witnesses, a police report, a death certificate and some photographs. At the date of writing, case no. 4299 is still deemed 'data insufficient' (B. Gillett, ISAF, pers. comm.). It is only under the condition of accurate identification and account of the circumstances of the attack for each entry in the ISAF database, that reliable information can then be extracted for meaningful ex-post facto analysis.

The identification and the estimated size of the shark species involved in an attack should rely on objective information. Ideally, the shark, or a good photograph of it, should be identified by a shark specialist. Teeth embedded in the victim or in surrounding objects may also be diagnostic. However, in most cases, forensic identification can only rely on the aspect of the bite damage on the victim. Other information, for instance shark behaviour as reported by witness, has been used to identify the shark to species:⁹ this has proven unreliable, as we will demonstrate in this paper. The present case report is intended as a reappraisal of the Luengoni, 2007 case (ISAF no. 4299).

2. Case reappraisal

Detailed accounts of the attack, which took place in Luengoni (Lifou Island, New Caledonia) on 30 September 2007, have been written.^{4,9} The wound was ascribed to "a single large bite with a maximum length of about 40 cm".⁹ Disputable points are enumerated in the following. It was reported "that the teeth did not form a continuous cutting edge but instead were separated by more or less wide spaces";⁹ also, the shark had been reported to "jump out of the water" at the moment of the attack,⁹ prompting authors E. Clua and B. Séret to identify the attacker as a great white shark, a shark species that seasonally occurs in New Caledonian waters.⁷ These authors reported that the "femur bone [was] broken at the level of the hip".⁹ The wound on the inner thigh was described as "broadly curved and present[ing] clear cut sections (made by large flat teeth) separated by small ragged pieces of skin/flesh (indicating that the teeth did not form a continuous cutting edge but instead were separated by more or less wide spaces)".⁹ Furthermore, the outer part of the bite was described as: "broadly curved and show[ing] similar aligned flat sections separated by small rags of skin/flesh, but somewhat shredded"⁹ although no photographic evidence was provided by the authors to support the latter claim and they did not carry out any examination of the body of the victim. The authors also recalled that the single bite inflicted on the victim was a tactic known from great white shark ('bite-and-spit' behaviour) and claimed that "a tiger shark would not have released its mouth contents but would have swallowed it instead".⁹

Two of us (PT, CM) examined the body of the victim on 03 October 2007, soon after it had been transferred to the mortuary in Nouméa. We here provide in Supplementary Material high-resolution photographs of the wound, taken by PT. The outer part of the wound is here presented in picture for the first time (Fig. 1). The diameter of the bite, measured by us, was 38 cm and the bite circumference, deduced from the diameter by assuming a circular shape of the jaw, was 59.7 cm. In contrast with E. Clua and B. Séret's report,⁹ we observed that the femur was neatly cut below trochanter minor, as if it had been sawed, not actually broken. We also observed that the edge of the wound was continuous and no wide spaces between teeth were obvious (as evident also from Figure no. 3 of Reference 9, though contrary to the interpretation provided in it). Moreover, the description of the outer part of the wound as presented previously⁹ was not correct, as actually a single clear cut was present without shredding (Fig. 1). Hence, both the outer and inner sides of the wound showed similarly continuous cuts with a well-defined edge. This hitherto neglected but crucial information indicates that the attacking shark had homodontous jaws, which excludes the great white shark as a possible attacker as explained in the following.⁴ Of the three species capable of a large bite of this size, both the great white shark and the bull shark possess markedly heterodontous jaws.^{4,11} On their dorsal side, wounds inflicted by great white sharks are clear-cut and quasi-circular while their ventral side is characterized by deep gashes and shredding, as observed on the body of elephant seals (*Mirounga angustirostris*) bitten by great white sharks on the coast of California.¹² This, clearly, was not observed on the Luengoni victim's body. The only shark with homodontous jaws able to inflict a large, symmetrical bite such as that observed on the Luengoni victim is the tiger shark (*Galeocerdo cuvier*).⁴ Wounds inflicted by tiger sharks are indeed symmetrical, as observed on the body of Nari, a bottlenose dolphin (*Tursiops aduncus*) bitten by a tiger shark off Moreton Island, Australia.¹³ In addition, a tiger shark's tooth has a shape similar to that of a can-opener and its edges are strongly serrated:^{4,12} these features obviously serve the purpose of sawing through hard material, like turtle shell, dolphin tailstock or whale skull and bones,¹⁴⁻¹⁷ thus explaining the regular aspect of the section of the femur of the victim.

E. Clua and B. Seret's report⁹ partially relied on a second-hand, incomplete set of photographs lacking the depiction of the posterior part of the wound. In contrast, the present interpretations primarily relied on external examination of the body of the victim. Photographs are here presented to illustrate our de visu observations and not as primary evidence. Some of the additional information presented in Reference 9 is dubious. For instance, the purported observation of the "shark jumping out of the water to reach the victim"⁹ (a well-known behaviour in great white shark)^{18,19} was not mentioned in the police interview of the main witness,²⁰ who subsequently confirmed to us that the declaration she made to the police was accurate and complete. Moreover, the water depth at the site of the attack (2.50 m) is unlikely to be sufficient for a large shark to gain sufficient momentum to be able to project itself out of the water.^{18,19} Therefore, there was actually no evidence of even the possibility of leaping behaviour in the Luengoni shark. The 'bite and-spit' or 'grab-release' hypothesis, which has been initially proposed to explain the predatory behaviour of great white sharks on marine mammals and turtles,^{21,22} is a tactic also observed or inferred for tiger sharks preying on dolphins.^{14,16} In one instance, it was inferred that the tiger shark first severed the tailstock of a juvenile bottlenose dolphin (*Tursiops* sp.) before resuming its attack by removing a chunk of its belly.¹⁶ In another case, a tiger shark that followed a group of swimming pantropical spotted dolphins (*Stenella attenuata*) swiftly inflicted a single powerful bite to one dolphin of the pod, severing its tail and causing its death by either haemorrhagic shock or drowning (or both).¹⁴

Lastly, the qualification of the attack as “unprovoked”⁹ needs to be re-evaluated, since it has been established that the very days before the attack, a traditional wedding ceremony had taken place in Luengoni village, and that carcasses and offal of pigs, goats, poultry and fish had been disposed off from the shore of Luengoni Bay.³

3. Conclusion

Behavioural aspects of the Luengoni shark attack are reminiscent of a type of predatory behaviour that has been documented in both tiger sharks and great white sharks. Therefore, behavioural evidence was uninformative and the only diagnostic, first-hand information to be used in the Luengoni case was the characteristics of the wound on the body of the victim. The diagnostic features of the wound were its large size and its dorso-ventral symmetry, indicating homodontous jaws. These two features combined clearly designate the tiger shark as the only possible attacker in this case.
