Received 27 August, 2018; Accepted 4 October, 2018

Piliostigma reticulatum shrub is a native legume found in fallow areas in dry and semi-dry savanna soil and is used in intercropping systems. The aim was to understand the functioning of the rhizosphere, particularly the involvement of symbiotic and free living-N fixing bacteria. Soil extracts collected from P. reticulatum roots were sampled in two contrasting areas and endophytic bacterial communities were isolated using three trap host species (F. albida, A. bivenosa and V. seyal). Potential endophytic bacteria (PEB) were characterized by RFLP, nifH PCR and by 16S rRNA gene sequencing. The subsequent behavior of P. reticulatum was monitored in vitro by measuring leaf weight, biomass and chlorophyll content, after inoculation with PEB. This approach enabled isolation of 59 bacteria belonging to different genotypes. The most abundant genera were Cohnella (27.65%) among which 11 isolates clustered together and could represent a new species closely related to C. plantaginis. The other dominant genera were Paenibacillus (21.27%), Bradyrhizobium (14.89%) and Ensifer (8.5%). The nitrogen fixing gene (nifH) was detected in 21 strains and in particular, detected in a single isolate (PZS_S04) close to Cohnella xylanilytica. The strains PZS_S05 (Ensifer) and PZG_A18 (Cohnella) significantly increased certain parameters including shoot dry weight, shrub height at 90 days and photosynthetic activity (SPAD), compared to non-inoculated controls. The result obtained showed that soil under the influence of P. reticulatum roots harbored a specific diversity of endophytic bacteria including two free living-N fixing bacteria with the potential to improve the growth of P. reticulatum in natural conditions.

Key words: Piliostigma reticulatum, microbiology, phylogeny, Potential endophytic bacteria (PEB), nitrogen-fixing bacteria.

INTRODUCTION

The rhizosphere of legumes is a fertile zone due to the accumulation of different organic compounds released...
from their roots (Bowen and Rovira, 1999; Barea et al., 2005). For this reason, the soil under the influence of plant roots is very favorable for the growth and activity of microbial communities, which plays a significant role in carbon and nitrogen biogeochemical cycles (Vitousek and Howarth, 1991; Toal et al., 2000). Plant-associated bacteria can also have a beneficial impact on legume nutrition as nitrogen is biologically fixed by nitrogen-fixing symbiotic bacteria or by free living-N fixing bacteria in the rhizosphere. Nitrogen-fixing symbiotic bacteria (or rhizobia) can establish symbiotic relationships and can reduce the atmospheric nitrogen (N\textsubscript{2}) into ammonium (NH\textsubscript{4}\textsuperscript{+}), which can be directly assimilated by plants. In addition, it is known that rhizobia can behave like non-symbiotic endophytes of legumes or non-legume plants such as maize, rice, cotton and wheat (Ueda et al., 1995; Engilhard et al., 2000) and can establish non-specific relationships with plants. However, the effects of the micro-environment formed by the plant rhizosphere on nitrogen-fixing symbiotic bacteria diversity remain unclear, in particular, on the subfamilies of Leguminosae such as Cercidoideae (LPWG, 2017). This new subfamily is proposed by the Legume Phylogeny Working Group (LPWG) currently contains 12 genera (including Pilostigma genus) which mainly grow in tropical regions and have no root nodules (LPWG, 2017).

\textit{P. reticulatum} (DC.) Hochst is a pioneer species, able to grow on degraded land, and to increase plant succession by other species. The shrub induces spatial heterogeneity of soil chemical properties in arid and semi-arid environments (Diedhiou et al., 2009). Twigs and wood fragments of \textit{P. reticulatum} can also be used as dead ground cover (Diedhiou et al., 2009; Yélémou et al., 2013), to restore degraded land and improve crop yields (Bright et al., 2017). The use of \textit{P. reticulatum} residues may improve the ability of soils to respond to saline conditions (Sall et al., 2015). Soil under the influence of the shrub is described in terms of islands of fertility under the influence of \textit{P. reticulatum} (Wezel et al., 2000; Housman et al., 2007) due to a shift in soil microbial community diversity and enzymatic functions beneath the rhizosphere of the shrub compared to bulk soil (Diedhiou et al., 2009; Diedhiou-Sall et al., 2013). However, how microbial communities including symbiotic and non-symbiotic bacteria present in the soil under the influence of \textit{P. reticulatum} contribute to the growth of this shrub remains unclear. Some non-symbiotic endophytic bacteria have several beneficial effects on host plants. During colonization of the roots or soil rhizosphere, they stimulate and promote plant growth (Bai et al., 2003; Aserse et al., 2013). Microorganisms isolated from the rhizosphere of various crops have been shown to produce phytohormones such as indole acetic acid as secondary metabolites. The different biosynthetic pathways of this hormone are already well described for some bacterial genera such as Azospirillum, Azotobacter and Paenibacillus (Shokri and Emiztai, 2010). Endophytes play an important role in the degradation of plant litter and organic pollutants, which in turn, actively increases soil fertility (Wang and Dai, 2011). Some works (James et al., 2000; Turner et al., 2013) suggest that endophytic bacteria may increase nitrogen fixation.

The aims of the study were to understand the functioning soil under the influence of \textit{P. reticulatum} to: 1) evaluate the diversity of bacteria (symbiotic and non-symbiotic nitrogen fixing); and 2) study their impact on the growth of \textit{P. reticulatum} plants.

\section*{MATERIALS AND METHODS}

\section*{Sites and sampling of shrub}

This study was performed at two climatically and environmentally contrasted sites. The first site Zone Sudano-Sahelian (ZSS) is located near Ndassasse (14°55′N-16°49′W), Senegal. The area is characterized by a Sudano-Sahelian climate with mean annual rainfall ranging from 400 to 600 mm. The second site Zone Sudano-Guinean (ZSG) is located in the village of Sare Yorobana (12°50′N-14°50′W), Senegal. This southern area is characterized by a Sudano-Guinean climate with more rain, and the mean annual rainfall reaches between 800 and 1,200 mm. At each site, three \textit{P. reticulatum} shrubs ~1.5 m high were chosen and the soil under the shrub was sampled to a depth of 25 cm. The soil samples were composed of rhizosphere soil and extended to soil located around the roots, as soil adhering to the roots and around the roots are both under the influence of the shrub.

\section*{Trapping potential endophytic bacteria (PEB) associated with \textit{P. reticulatum.}}

The PEB present in the soil under the influence of \textit{P. reticulatum} roots were studied using three trap host species (\textit{Faithherbia} (syn Acacia) albida, \textit{A. bivenosa} and \textit{Vachellia} (syn Acacia) seyal) belonging to the mimosoid clade and the subfamily of Caesalpinioideae (LPWG, 2017). Firstly, the seeds of these species were scarified and the surface sterilized by soaking them in 95% (v/v) sulfuric acid for 30 min. The seeds of \textit{F. albida}, \textit{A. bivenosa} and \textit{V. seyal} were thoroughly rinsed and soaked in sterile distilled water for 5 h, 7 h and 2 h for \textit{F. albida}, \textit{A. bivenosa} and \textit{V. seyal}, respectively. The seeds were left to sprout in Petri dishes containing 2% agar and then incubated at 28°C for 48 h. The sprouting seeds were transferred under sterile conditions to Gibson tubes (Gibson 1963) containing a sterile Jensen nitrogen-free nutrient medium adjusted to pH 7 (Vincent 1970). The seedlings in the tubes were maintained in a growth chamber in the following conditions (at 28 ± 1°C with a 16 h day/8 h night photoperiod, relative humidity of 45 ± 5% and a 74 μmol.m⁻².s⁻¹ light intensity). After one week, the young plants were inoculated with 5 ml soil suspensions (10 g of soil in 90 ml of physiological water) influenced by \textit{P. reticulatum}. Four repetitions were performed for each trap host species and four non-inoculated plants were used as controls.

Isolation of endophytic bacteria

After 45 days of growth, the nodules growing on the roots of the trap host species (F. albida, A. bivenosa, V. seyal) were harvested and enumerated. The nodules were then sterilized using a solution of HgCl₂ (2% w/v) for 3 min, followed by several soakings in sterile water. The endophytic bacteria were isolated by streaking a loop-full of the crushed nodule on yeast mannitol agar (YMA) medium (Vincent, 1970) and incubated at 28°C for 24 h to 72 h. Similar morphological colonies to rhizobia were picked out on YMA. Pure colonies were obtained after successive transplanting of single colonies on new plates.

After the strains were identified by sequencing, sub-groups of strains showing strong similarity with known bacterial species belonging to the family of Rhizobiaceae and Bradyrhizobiaceae were retested for their ability to nodulate their respective hosts, using Gibson tubes (Gibson, 1963) as described above.

DNA extraction and PCR of 16S rRNA and nifH genes

The genomic DNA of isolated bacteria was extracted using the Nucleospin Tissue 96 kit (Macherey Nagel) according to the manufacturer's instructions. All PCR were performed using the kit Illustra Hot Start Mix RTG (GE Health care, Bucking Hampshire, UK). The 16S rRNA gene was amplified using pA (AGAGTTTGAATCCTGCGTCA) and pH (AAGGAGGTGGTCACTCCAGCGGCA) primers (Edwards et al., 1989). The reaction was carried out with 35 cycles as follows: denaturation for 15 s at 94 °C, primer annealing for 30 s at 55°C, and polymerization for 90 s at 72°C, plus a preheating phase of 5 min at 94°C and a terminal extension for 3 min at 72 °C. The nifH gene was amplified using the primers PolR (ATSGCCATCATYTCRCCGGA) and PolF (TGCGAYCSCAARGCBGACTC) (Poly et al., 2001) under the following conditions: 30 cycles each, denaturation for 60 s at 94 °C, annealing for 60 s at 60 °C, and elongation for 60 s at 72 °C. The cycles began with 95 °C denaturation for 15 min and ended with an extension phase for 10 min at 72 °C. PCR products were submitted to electrophoresis on 1% agarose gel for 30 min at 100 V and stained with ethidium bromide.

RFLP of 16S rRNA gene

The PCR products of the 16S rRNA gene were digested with two restriction endonucleases (Fast Digest enzyme) Haelll and Mspl (Thermo Fisher Scientific). For each PCR product, digestion was carried out in a volume of 20 μl containing 0.5 μl of enzyme, 2 μl of buffer, 5 μl of PCR products and 12.5 μl of water, and the mixtures were incubated at 37 °C for 30 min. Ethidium bromide was performed on 2% agarose gel for 60 min at 100 V and stained with ethidium bromide. The results were analyzed by comparing bands, which enabled the clustering of profiles according to the position and size of bands.

Taxonomic identification of endophytic bacteria

The PCR products of 16S rRNA gene of isolates were sequenced (GATC Biotech, Constance, Germany). The nucleotide sequences were verified and corrected using SeqMan Pro (DNASTAR - Software for Molecular Biology - Sequence Analysis) and aligned with Clustal W Multiple alignment (Thompson et al., 1994). The resulting sequences were blasted against reference sequences in the NCBI database (http://www.ncbi.nlm.nih.gov/Blast.cgi). The evolutionary history was inferred using the neighbor-joining method (Saitou and Nei 1987). Evolutionary analyses were conducted in MEGA6 (Tamura et al., 2013). The percentage of replicate trees in which the associated taxa were clustered together in the bootstrap test (1000 replicates) was shown next to the branches. All sequences were submitted to NCBI with accession numbers ranging from KY992880 to KY992923.

Growth of P. reticulatum in in vitro conditions

The seeds of P. reticulatum were scarified in sulfuric acid for 1 h, then rinsed several times and soaked for 24 h in sterile water. The seeds were grown on 2% agar at 28°C for 48 h and then transferred into Gibson tubes. The seedlings in tubes were maintained in a growth chamber under the conditions described above. After 5 days, the seedlings were inoculated with 1 ml of bacterial culture (approximately 109 cfu ml⁻¹) of each of the seven PEB. Five replicates were made for each strain and five non-inoculated plants were used as controls. The level of free-nitrogen nutritional plant was readjusted regularly in the tubes.

After three months of growth, the height of the plants was measured and chlorophyll content of the leaves was measured with a SPAD-502 chlorophyll meter (SPAD-502, Minolta Corp.; Ramsey, NJ, USA). Shoots and roots were harvested separately and dried at 70 °C to constant dry weight, after which dry weight was measured.

Statistical analyses

Statistical analyses were performed on the different growth parameters to investigate the effect of each treatment. ANOVA was followed by comparison with controls using Dunnett’s test. The multcomp package (Hothorn et al., 2008) was used with one-sided. Dunnett tests (strains tested had positive effects on these growth parameters).

RESULTS

Capture of PEB from soil under the influence of P. reticulatum

Soil under the influence of P. reticulatum sampled from the two contrasting sites contained different numbers of nodules depending on the three trap plants (F. albida, A. bivenosa and V. seyal). A total of 140 nodules were recovered at Sudano-Sahelian site (ZSS), of which 83 came from the roots of F. albida, 43 nodules from the roots of V. seyal and only 14 from the roots of A. bivenosa. At the Sudano-Guinean site, a greater number of nodules (412) formed on the roots of the three trap plants. A total of 337 nodules formed on the roots of F. albida, 74 nodules on the roots of V. seyal and only one nodule formed on roots of A. bivenosa. Next, 10 nodules were sub-sampled on each trap plant to isolate the PEB, except for A. bivenova from the Sudano-Guinean site. Morphological screening under a magnifying glass enabled the selection of 59 PEB including 26 from the site. Sudano-Sahelian site and 33 from the Sudano-Guinean.

The 16S rRNA gene PCR was performed on the 59 PEB. RFLP profiles revealed 14 different clusters (I to
XIV) based on the number and size of the bands (Table 1). Cluster I was the most abundant (34%) and was found with three plant hosts. Cluster II was the second biggest group with 18% of profiles most isolated from nodules of *F. albida*. The profile of cluster IV was characteristic of the Sudano-Guinean site and isolated from nodules of *V. seyal*. The other groups were poorly represented, regardless of the host plant or the origin of the soil.

The PCR of *nifH* gene was also performed on 59 PEB, of which 35.6% (21 isolates) showed a positive amplification signal (Table 2), with nine positive signals of PEB at the Sudano-Sahelian site and 12 at the Sudano-Guinean site. According to the three trap host species used, the 21 *nifH* genes were distributed as follows: 15 positive signals (71.4%) were obtained with *V. seyal*; four positive signals (19%) with *F. albida* and only two positive signals (9.5%) with *A. bivenosa*.

### Taxonomic diversity of potential endophytic bacteria (PEB)

The results (Table 2) revealed 25 different species of PEB distributed in four clusters (Figure 1). These PEB belong to nine (9) families: *Paenibacillaceae*, *Bacillaceae*, *Rhizobiaceae*, *Phyllobacteriaceae*, *Bradyrhizobiaceae*, *Moraxellaceae*, *Pseudomonadaceae*, *Burkholderiaceae* and *Micrococccaceae*.

Cluster I included 25 strains and was separated in two sub-clusters (SC1 and SC2). The SC1 group contained 22 strains with strong similarity to the *Paenibacillaceae* family. Thirteen (13) strains were closely related to the *Cohnella* genus, most of which (11) were grouped in a subgroup closely related to *Cohnella plantaginis* isolated from plantain in China (Wang and Dai 2011). One strain (PZG_A13) was close to *C. rhizosphaerae* isolated from the rhizosphere environment of *Zea mays* (Kämpfer et al., 2015) and one (PZS_S04) formed a set with *C. xylanilytica* (Khiangam et al., 2010). Nine strains were closely related to *Paenibacillus glycanyliclyticus* (Kajiyama et al., 2002), to *P. humicus* (Vaz-Moreira et al., 2007), and to *P. rigui*, isolated from a freshwater wetland (Baik et al., 2011). The SC2 grouped three strains, including two strains (*Bacillus aryabhatai* and *Bacillus sp strains* (HM212416.1)), closely related to the *Bacillus* genus and one strain close to *Rummelibacillus suwonensis*. These strains were isolated from different environments; *Bacillus aryabhatai* was isolated from the rhizosphere region of *Lemna sp* of East Kolkata wetlands of the Indian sub-continent (Ray et al., 2012), *Bacillus sp strains* (HM212416.1) and *Rummelibacillus suwonensis* isolated from soil collected in a mountain area of South Korea (Her and Kim, 2013).

Cluster II contained a single isolated strain (PZS_A07), which was closely related to *Kocuria marina* sp, which is a novel Actinobacterium isolated from marine sediment (Kim et al., 2004).

Cluster III contained 12 strains separated in two sub-clusters (SC3 and SC4). Five strains were grouped in the SC3 cluster with almost 100% similarity with *Bradyrhizobium elkanii* (Kuykendall et al., 1992) and *Bradyrhizobium liaoningense* isolated from the root
Table 2. PCR signal of the nifH gene and sequence similarities of 16S rRNA gene of Potential Endophytic Bacteria (PEB) isolated from nodules of three trap host species (Faidherbia albida, Acacia bivenosa and Vachellia seyal).

PEB: Potential endophytic bacteria; (+): positive signal of nifH; (-): negative signal of nifH; Twelve (12) other strains were not sequenced and the results by nifH amplification were as follows: PZG_A22 (-); PZG_S22 (-); PZG_S23 (-); PZG_S24 (-); PZG_S26 (-); PZG_S26 (+); PZG_S27 (+); PZG_S28 (+); PZS_A23 (-); PZS_A24 (-); PZS_S29 (-); PZS_S30 (-). Three slow sequences are not included in the table: PZG_S13 (+), PZS_S03 (+), PZS_A04 (+).
Figure 1. Phylogenetic tree of Potential Endophytic Bacteria (PEB) based on aligned sequences of 16S rRNA gene. Phylogeny history was inferred using the neighbor-joining method. Only bootstrap probability values >70% (1000 replicates) are shown at the branching points. Phylogenetic analyses were conducted in MEGA version 6; C: cluster; SC: sub-cluster.
nODULES OF SOYBEAN (AB698736). The SC4 grouped seven fast growing strains, which were close to Mesorhizobium plurifarium (de Lajudie et al., 1998), to Rhizobium giardinii sp isolated from Phaseolus vulgaris nodules (Amarger et al., 1997) and to Ensifer adhaerens (Casida Jr, 1982). Cluster IV contained six strains, which were close to different bacterial species: Pseudomonas azotoformans (Iizuka and Komagata 1963), Acinetobacter calcoaceticus (AJ888983), Ralstonia pickettii (Ralston et al., 1973), Caballeronia zhejiangensis (HE983367), and Paraburkholderia insulsa (KF733462).

Impact of PEB on the growth of P. reticulatum

In order to evaluate the impact of PEB isolated from soil under the influence of P. reticulatum, seedlings of the shrub were inoculated with seven strains (PZG_A17, PZG_A18, PZG_S09, PZG_S14, PZG_S02, PZG_S04 and PZS_S05), mainly chosen on the basis of the presence of the nifH gene (Table 2). After three months, P. reticulatum shrubs inoculated with the three strains significantly increased the chlorophyll contents of leaves measured by SPAD (Figure 2), compared to the inoculated shrub. These were strains PZG_A18 close to Cohnella, PZG_S14 close to Bradyrhizobium elkanii and to a lesser extent, PZS_S05 close to Ensifer (p < 0.001, p < 0.01 and p < 0.05 respectively). Analyses of plant height showed that (Figure 2) the endophytic bacteria PZS_S05 and PZG_A18 significantly improved (p < 0.001 and p < 0.01, respectively) the growth of the shrub, compared to controls. In terms of shoot dry weight (Figure 3), only the endophytic bacteria PZG_A18 differed significantly (p < 0.001) from inoculated plants. The dry weight of roots (Figure 3) revealed no significant difference between the inoculated plants and the controls, except for PZS_S05, which increased root weight (p < 0.05). In terms of total dry weight, no significant difference was observed between inoculated plants and controls (Figure 3). In total, the strains PZS_S05 close to Ensifer and PZG_A18 close to Cohnella induced a significant increase in certain parameters including dry weight of roots, growth at 90 days and photosynthetic activity, compared to the inoculated shrub.

DISCUSSION

The use of three host trap species (F. albida, V. seyal and A. bivenosa) provided access to the diversity of potential endophytic bacteria (PEB) present in the soil under the influence of P. reticulatum roots in two contrasting areas (one Sudano-Sahelian and one Sudano-Guinean). Indeed, the number of nodules formed on the roots of host plants showed that the soil from Sudano-Guinean site induced more nodules than the soil.
from Sudano-Saharan site. These differences seem to be due mainly to the contrasting soil properties (Table 3) at the two sites. In fact, soils from the two regions of Senegal used in this study are both sandy, but the soil from the Sudano-Guinean site had a higher percentage of silt and clay than the soil from the Sudano-Saharan site. Similar results were found using *Senegalia senegal* inoculated with soils from arid and semi-arid regions of Senegal (Bakhoun et al., 2014) and *A. saligna* inoculated with soils from northern and southern areas of Algeria (Amrani et al., 2010). As expected, the diversity of RFLP profiles was also higher in the soil from Sudano-Guinean site than the soil from Sudano-Saharan site.

On the other hand, the results showed that the number of nodules formed with *F. albida* was higher than the number obtained with *A. bivenosa* and *V. seyal* regardless of the origin of the soil. The largest number of taxonomic groups was obtained on *V. seyal* host despite the fact that the same number of nodules was sub-sampled. This is in agreement with the fact that *V. seyal* belongs to the group of plant species that can be nodulated by the *Ensifer* genus (*Sinorhizobium*) (Odee et al., 2002; Romdhane et al., 2005; Cordero et al., 2016; Sankhla et al., 2017) and *Mesorhizobium* (Diouf et al., 2007). In contrast, *A. bivenosa* and *F. albida* are frequently nodulated by the *Bradyrhizobium* genus (Odee et al., 2002; Perrineau et al., 2012; Sprent et al., 2017). Even though the trap plants are selective with respect to soil bacteria, they have the advantage of selecting endophytic bacteria, including Rhizobia, more easily.

The results showed that the isolated bacterial belonged to nine families: *Paenibacillaceae, Bacillaceae,
Rhizobiaceae, Phyllobacteriaceae, Bradyrhizobiaceae, Moraxellaceae, Pseudomonadaceae, Burkholderiaceae and Micrococcaeae. More than 60% of these bacterial species were denoted non-symbiotic bacteria. A similar study carried out by Burbano et al. (2015) found fewer families of bacteria associated with Colophospermum mopane. As P. recticulatum, Colophospermum mopane also belongs to the family of non-nodulate plants (LPWG, 2017). Thus, the trap species used in this study clearly revealed the presence of symbiotic and nitrogen-fixing bacteria (Mesorhizobium, Bradyrhizobium and Rhizobium) in soil under influence of P. reticulatum. In addition, all the strains identified as belonging to the large group of rhizobia were able to form nodules on roots of their respective host plants (data not shown). This shows that P. reticulatum is unable to form visible nodules, but could influence the bacterial diversity of soil. This is in agreement the work of Diedhiou et al. (2013) who used phospholipid fatty acid analysis (PLFA) of microbial communities and also reported that Gram-positive bacteria (non-symbiotic) were in the majority in the soil under the influence of P. reticulatum.

To study the growth of P. reticulatum in in-vitro conditions, nitrogen fixing genes among the isolated strains were investigated. Among nitrogenase proteins, the nifH sub-unit is the most conserved. In this study, the screening of 59 PEB showed that a little less than half the isolates produced positive signals to nifH gene amplification, including almost endophytic bacteria belonging to the rhizobia group (except PZS_S01, Rhizobium sp). The absence of amplification of the latter strain may be due to a sequence divergence between the primers used and the gene present in the genome. Strains closely related to Cohnella species were the most abundant endophytes sampled. The majority of these isolates clustered together with a high bootstrap value and was closely related to C. plantaginis. This cluster could represent a new Cohnella species (Figure 4). All the strains in this sub-cluster showed negative signals for the nifH gene. However, Wang et al. (2012) recently reported Cohnella plantaginis to be a novel nitrogen-fixing species, but by using the acetylene reduction assay. In contrast to this sub-cluster, PZS_S04, similar to Cohnella xylanitytica (97%), showed positive amplification of the nifH gene. C. xylanitytica is a xylan-degrading bacterium and was recently proposed as a new Cohnella species (Khianngam et al., 2010). It is known that many members of the Bacillus and Pseudobacillus genera are diazotrophic bacteria. This is certainly the case of strains PZW_S03, PZW_S16 (belonging to the Bacillus genus), PZW_A04 and PZW_S12 (belonging to the Pseudobacillus genus). In fact, the Bacillus genus also comprised a high percentage of endophytic bacteria associated with the roots of Colophospermum mopane (Burbano et al., 2015). Comparison of the results of this study and those of Burbano et al., showed that PEB from P. reticulatum were more diversified than those associated with the roots of Colophospermum mopane and Cohnella sp. was not found associated to with roots of Colophospermum mopane. The different approaches used in the two studies (direct isolation or functional approach) could explain these differences.

In addition, the presence of nitrogen-fixing species suggests that these species could be involved in the supply of nitrogen to the plant, as well as enriching the soil with nitrogen. These groups are frequently encountered in the nodules of legumes (Zakhiia et al., 2006). Their role in the nodules remains obscure, but they probably play a role in biological fixation in the nodules and/or beneficial effects via production of plant hormones that promote plant growth. In all, seven PEB were selected and inoculated on young plants of P. reticulatum. Compared to controls, PZS_S05 (Ensifer sp) and PZW_A18 (Cohnella sp) were able to significantly increase the height of the shrub. These two same strains also significantly increased chlorophyll contents, as is the case for PZW_S14 strain. Regarding dry weight, only strains PZW_A18 and PZW_S05 significantly increased dry shoot and root dry weight, respectively, but to a lesser extent. The mechanisms involved in these significant increases in plant growth should now be investigated, although many studies have shown that non-symbiotic endophytic bacteria can be used as inoculants to promote plant growth, nodulation, and to increase yields (Bai et al., 2003; Liu et al., 2010; Stajkovic et al., 2011). Stajković and collaborators (2011) also showed that shoot dry weight and nitrogen content in common bean plants were improved after co-inoculation of Rhizobiumphaseoli and Bacillus sp. On the other hand, it appears that the increase of chlorophyll (SPAD) increased dry weight of leaves for PZW_A18, whereas in contrary the dry weight of the roots is increased with PZW_S05. The current state of our knowledge on this shrub does not know the mechanism involved, which seems not related to bacterial strains. It will be interesting to test these strains in field conditions and to measure their impact on the growth of associated millet. As recently shown by Diakhaté and collaborators (2016) P. reticulatum appears to promote greater diversity of microorganisms in the root zone of cereal millet.

**Conclusion**

P. reticulatum is an important shrub for soil fertilization. Thus knowledge of bacterial diversity and their impacts on growth and nitrogen status of this shrub could help make better use of P. reticulatum in the arid and semiarid zones of the Sahel. The results of this study revealed that the soil under the influence of P. reticulatum is associated with greater bacterial diversity, the extent of which varies depending on its area of origin (northern or southern Senegal).

The methods used including trapping bacteria, PCR-
RFLP and 16S rRNA gene sequencing efficiently demonstrated that *P. reticulatum* exerts an impact on the bacterial communities of the soil. The strains PZS_S05 (*Ensifer*) and PZG_A18 (*Cohnella*) were able to improve *P. reticulatum* growth and increase chlorophyll content. These results pave the way for the use of the endophytic
bacteria / *P. reticulatum* association to improve the growth of the shrub.

**ACKNOWLEDGMENTS**

This work was carried out with the support of the French Embassy in Senegal (SCAC), PAPES (Support Project for the Promotion of Researchers and Teachers-researchers from Senegal), WAAPP (West African Agriculture Productivity Program), USAID / ERA (United States Agency for International Development / Education Research in Agriculture). The authors appreciate the Ampere laboratory of *Ecole Centrale de Lyon* (France), and the joint laboratory of microbiology (LCM) of Dakar. They are also grateful to Dr. Abdoulaye Soumaré, Omar Touré, Paul Tendeng and Mathieu Ndigue Faye for their technical help.

**CONFLICT OF INTERESTS**

The authors have not declared any conflict of interest.
